FEEDBACK TRADING‡

JÓN DANIELSSON* and RYAN LOVE
Financial Markets Group, London School of Economics and Political Science, UK

ABSTRACT

Order flow has been found to carry information to the market. When assessing how informative order flow is, the VAR methodology is typically employed, using impulse response functions. However, in such analyses, the direction of causality runs explicitly from order flow to asset return. If data are sampled at anything other than at the highest frequencies then any feedback trading may well appear contemporaneous; trading in period t depends on the asset return in that interval. The implications of contemporaneous feedback trading are examined in the spot USD/EUR currency market and we find that when data are sampled at the 1 and 5 minute frequencies, such trading strategies cause the price impact of order flow to be significantly larger than when feedback trading is ruled out. KEY WORDS: Market microstructure; impulse response functions; simultaneous equation systems

Order flow, one way buying or selling pressure, has a contemporaneous impact on prices, while at the very highest frequencies, the converse is not true. However, when aggregated over time, order flow and prices can be expected to impact on each other simultaneously, a phenomenon we call contemporaneous feedback trading. The existence of contemporaneous feedback trading implies that such models cannot be estimated with traditional techniques. This is unfortunate, since empirical models with feedback trading can be expected to give firmer support for theoretical models than models that ignore such trading strategies. In this paper, we argue that feedback trading is an inevitable consequence of time aggregation of order flow models, and propose an estimator of such models by using instrumental variable techniques. We find that the price impact of trades is much stronger when feedback trading is incorporated, further supporting market microstructure theories generally, and the validity of the order model specifically.

It is well known in the theoretical microstructure literature that order flow conveys private information to the market as a whole. In this way, information is aggregated via the trading process implying that order flow has permanent effects on prices. See Kyle (1985), Glosten and Milgrom (1985), Easley and O’Hara (1987), and Evans and Lyons (2002) for examples of such models. These models imply that if trades carry private information then the informativeness of trades can be accessed by their price impact. Furthermore, in empirical models when data are employed at the very highest frequencies, order flow, by definition, can only be affected by the lags of price changes. However, when data are aggregated, transactions and order entry are simultaneous, frustrating empirical investigations.

The existence and profitability of feedback trading strategies has been considered in a number of papers. De Long et al. (1990) build a model of feedback trading with rational speculators who will buy (sell) when the price rises (falls). The profitability of a number of feedback trading strategies in stock markets is considered in Jegadeesh and Titman (1993) and the existence of high-frequency positive feedback trading in the US treasury market is documented in Cohen and Shin (2003).

The most common methodology for empirically assessing the informativeness of order flow, is the vector autoregressive (VAR) model of Hasbrouck (1991). His model was originally applied to data at the tick-by-tick frequency, where the direction of causality runs explicitly from order flow to asset price returns. Hasbrouck introduces a shock to the trading process, representing private information, and computes the cumulated effect on the asset return. The greater the cumulated effect, or impulse response, the more information trades are argued to carry. These VAR models have become standard in the microstructure literature; recent examples include Dufour and Engle (2000) and Engle and Patton (2004) for stocks, Evans (2002) and Payne (2003) for currencies and Cohen and Shin (2003) and Green (2004) for treasuries. In the VAR framework, the asset return in period $t$ is regressed on contemporaneous order flow (date $t$) as well as lagged returns and order flows (dated $t-1$ or earlier), whereas order flows are only regressed on lagged returns and flows; order flows at date $t$ do not depend on contemporaneous asset returns.

These models therefore rule out contemporaneous feedback trading, an assumption which is overly restrictive when the data are sampled at anything other than at the highest frequencies. If traders have the ability to respond to price changes and trade before the end of the time interval used in the empirical investigation, then order flows will indeed cause asset price changes within that period, but these price changes may then feed back into order flows in the same interval. A shock to order flows within period $t$ may well cause a change in the asset price within that interval. If other traders react to this price change by buying or selling the asset themselves in that period, perhaps because they expect a wave of trading activity that pushes the price in one direction or another, this significantly affects market dynamics and estimates of trade informativeness. Therefore, a model which does not allow contemporaneous feedback trading will bias any estimates of how much information trades actually carry. If a positive order flow shock causes an increase in the asset price, which in turn causes an increase in order flows via feedback trading within that period, the total effect/price impact of the order flow shock will be higher than when feedback trading is ruled out. Alternatively, if there exists negative feedback trading, perhaps because of expected return reversals of the initial asset price change, the ultimate price impact of the trade will be smaller than the non-feedback case.

The reason for ruling out feedback trading in empirical models with aggregated data is that without such a restriction, the model cannot be estimated since the VAR becomes unidentified. By allowing returns to depend on order flow but ruling out the converse, the two equation VAR in returns and order flows becomes a recursively ordered structural VAR, which is just identified when the variance/covariance matrix of the residuals is restricted to be diagonal. However, as we show in Section 1, when data are aggregated from tick-by-tick to any lower frequency, contemporaneous feedback trading is inevitable. Imposing the restriction that order flows do not depend on contemporaneous asset returns then represents a mis-specification of the empirical model and is therefore likely to result in biased parameter estimates and incorrect inference.

However, it is not possible to estimate the simultaneous impact of order flows and prices on each other in the VAR model since, in the standard setup, not enough information is available for the VAR's identification. In order to identify both structural parameters, additional information is required and we suggest that sufficient information can be obtained from statistics (typically order flows or returns) from related assets or markets. This additional information can be used to identify and estimate the structural VAR in a very efficient manner through standard instrumental variables methods. In so far as many assets, whether they are currency, stocks or bonds, have a number of assets related to them, it seems likely that information should be readily available. This could then be used by the econometrician in order to estimate an otherwise unidentified model and hence allow for contemporaneous feedback trading. In the case of stocks, when trying to estimate a feedback trading VAR for IBM, one could try using statistics based on Hewlett Packard flows and returns for example, or any stock in the same or related industry. The question of which instruments to use is simply an empirical one. One may simply choose those instruments found to be strongly correlated with the endogenous right-hand side regressors.

We apply our instrumental variables VAR methodology to the spot USD/EUR (US dollar per euro) foreign exchange market since this is a very active market and provides a natural testing ground for our hypotheses of contemporaneous feedback trading. The data are taken from the Reuters D2000-2 electronic
trading system, one of the two dominant brokered trading platforms used in the inter-dealer spot FX market and cover the 8-month period from 1 December 1999 to 24 July 2000. In order to estimate the structural, feedback VAR for the USD/EUR market we use instrumental variables, where the instruments are statistics obtained from the closely linked markets of USD/GBP (US dollar per pound sterling) and GBP/EUR (pound sterling per euro). It is clear that the USD/EUR rate should, in the absence of arbitrage, equal the USD/GBP rate multiplied by the GBP/EUR rate. Statistics obtained from these markets, in particular returns and order flows, may then be correlated with the endogenous variables for which we are trying to instrument, i.e. USD/EUR returns and flows.

In order to evaluate the importance of the feedback trading parameter, we consider two sampling frequencies; 1 and 5 minutes. From both frequencies we estimated the VARs with and without feedback trading and calculated impulse response functions (IRFs) following an order flow shock, representing private information, in order to assess the informativeness of trades.

We find that for the 1 minute frequency, the feedback trading parameter in the structural VAR is positive and significant at the 1% level and the IRF following an order flow shock is larger when feedback trading is permitted. However the difference between the restricted and unrestricted IRFs is not significantly different from zero, at the 5% level. At the 5 minute frequency, the feedback trading parameter in the VAR is quantitatively large and significant at the 5% level, and the impulse response without feedback trading is significantly below that when feedback trading is permitted. This suggests that in the case of spot FX markets, feedback trading is prevalent and has significant implications when examining the price impact/informativeness of order flows, especially when the data are sampled at the lower/5 minute frequency. For the spot FX market considered in this exercise, feedback trading is positive, i.e. order flow in one period depends positively on the asset return in that period.

We demonstrate in a theoretical context in Section 1 that omitting feedback trading in aggregated data will result in a mis-specified model and will bias the estimated impact of order flow on prices. This is confirmed in our empirical exercise where we show that feedback trading is a significant concern for empirical order flow models. By employing appropriate instruments, we show that in high frequency foreign exchange data, there exists positive contemporaneous feedback trading: order flow in one period depends positively on the return experienced within that period. This results in the price impact of an order flow shock being significantly greater than when one imposes a recursive ordering of the VAR. Private information, in the form of unanticipated order flow shocks, then has a larger impact on returns than previously believed, i.e. trades carry more information than previous estimates suggest.

The rest of the paper is organized as follows. Section 1 motivates the need to model contemporaneous feedback trading when data are aggregated at any level. Section 2 introduces the model to be estimated and describes the standard techniques to be employed as well as explanations as to how to obtain analytical confidence bounds for the IRFs. Section 2 also discusses the choice of instruments used. Section 3 presents the regression results and reports the IRFs. Section 4 discusses our findings, placing them within the existing finance literature and Section 5 concludes.

1. THE INEVITABILITY OF CONTEMPORANEOUS FEEDBACK TRADING IN AGGREGATED DATA

In this section, we show how contemporaneous feedback trading can result simply from considering aggregated data. By definition, contemporaneous feedback trading, whereby order flows at date \( t \) depend on date \( t \) asset returns, cannot occur in tick-by-tick data; a trader can only respond to a price change once the price has indeed changed. Assume, without loss of generality, that returns and flows can be characterised by a VAR with only 1 lag. The VAR model, originally introduced by Sims (1980) and implemented in the microstructure literature by Hasbrouck (1991), is a simple statistical framework that allows us to examine the relationships between asset returns and trading activity; more specifically, order flows. Hasbrouck originally applied the model to US equity data where the data were sampled in ‘transaction time’, i.e. tick-by-tick data were used. In what follows, assume the data are sampled at a
sufficiently high frequency so that contemporaneous feedback trading is ruled out. This could be tick-by-
tick, 10 second or even 1 second data for very active markets.\(^4\) Since the possibility of contemporaneous
feedback trading is ruled out, the system of equations can be written as
\[
\begin{align*}
R_t &= \alpha_t + \beta F_t + \phi_{11} R_{t-1} + \phi_{12} F_{t-1} + \varepsilon_t^R \\
F_t &= \alpha_t + \phi_{21} R_{t-1} + \phi_{22} F_{t-1} + \varepsilon_t^F
\end{align*}
\]  
(1)

where \(R_t\) is the return on the asset in period \(t\), defined as the log first difference of the price, \(F_t\) is the order
flow in period \(t\); the number of buyer less seller initiated trades in that interval and \(\varepsilon_t^R\) and \(\varepsilon_t^F\) are serially
uncorrelated, independent errors with variances \(\sigma_{\varepsilon^R}^2\) and \(\sigma_{\varepsilon^F}^2\), respectively. The system can be written as a
structural VAR:
\[
\begin{bmatrix}
1 & -\beta \\
0 & 1
\end{bmatrix}
\begin{bmatrix}
R_t \\
F_t
\end{bmatrix}
= \begin{bmatrix}
\alpha_t \\
\alpha_t
\end{bmatrix}
+ \begin{bmatrix}
\phi_{11} & \phi_{12} \\
\phi_{21} & \phi_{22}
\end{bmatrix}
\begin{bmatrix}
R_{t-1} \\
F_{t-1}
\end{bmatrix}
+ \begin{bmatrix}
\varepsilon_t^R \\
\varepsilon_t^F
\end{bmatrix}
\]

\[
\Rightarrow Q y_t = \alpha + \phi y_{t-1} + e_t, \quad \text{Var}(e_t) = \Omega = \begin{bmatrix}
\sigma_{\varepsilon^R}^2 & 0 \\
0 & \sigma_{\varepsilon^F}^2
\end{bmatrix}
\]  
(2)

where \(y_t = [R_t, F_t]'\) and \(e_t = [\varepsilon_t^R, \varepsilon_t^F]'\), \(t = 1, \ldots, 2T\). What we wish to do is to move from a structural VAR
at a high frequency, \(t\), to a structural VAR where the frequency is halved (frequency \(\tau\)).\(^5\) However, in order
to do this, (2) must be converted into a reduced form and put into state space representation. Aggregation
can then be performed using the methods in Harvey (1989). The reduced form of (2), at the frequency, \(t\), is clearly
\[
y_t = \mu + Q^{-1}\phi y_{t-1} + Q^{-1}e_t, \quad t = 1, \ldots, 2T
\]  
(3)

where \(\mu = Q^{-1}\alpha\) and the corresponding reduced form at the frequency, \(\tau\), where \(\tau = 2t\), is shown in Section
A.1 to be
\[
y_t = \mu^+ + Ay_{t-1} + e_t, \quad \tau = 1, \ldots, T
\]  
(4)

where \(A = Q^{-1}\phi(I_2 + Q^{-1}\phi)\). Since returns and order flows are both flow variables, as opposed to stocks,
then the period \(\tau\) (low frequency) return is simply the sum of the two \(t\) period returns in that interval, and
similarly for order flows. The variance of \(e_t\) is given by
\[
\text{Var}(e_t) = G\Omega G' + Q^{-1}\Omega(Q^{-1})'
\]  
(5)

where \(G = (I_2 + Q^{-1}\phi)Q^{-1}\). To convert (4) into a structural VAR, we first factorise the variance of \(e_t\). This
is done in (6).
\[
\text{Var}(e_t) = [G \quad Q^{-1}]
\begin{bmatrix}
\Omega & 0 \\
0 & \Omega
\end{bmatrix}
\begin{bmatrix}
G' \\
(Q^{-1})'
\end{bmatrix}
= P\Omega P'
\]  
(6)

If we premultiply (4) by \([I_2, I_2]P^+\), where \(P^+\) is the Moore–Penrose inverse of the \(2 \times 4\) matrix \(P, P^+ = (PP')^{-1}P\), then the structural form can be written as
\[
[I_2, I_2]P^+y_t = [I_2, I_2]P^+\mu^+ + [I_2, I_2]P^+Ay_{t-1} + [I_2, I_2]P^+e_t
\]  
(7)

The variance of the error vector in the structural form is now
\[
\text{Var}([I_2, I_2]P^+e_t) = 2\Omega
\]  
(8)

Equation (7) therefore has the appealing property that the variance of the error (return or flow) at the \(\tau\)
period frequency is twice that of the error at the \(t\) period frequency.\(^6\) In order to solve for the structural
parameters in (7), note that if we let $x_t = P^+ y_t$, then $x_t$ is the solution to

$$
\begin{bmatrix}
g_{11} & g_{12} & 1 & \beta \\
g_{21} & g_{22} & 0 & 1 \\
\end{bmatrix}
\begin{bmatrix}
x_{1t} \\
x_{2t} \\
x_{3t} \\
x_{4t} \\
\end{bmatrix}
= \begin{bmatrix}
R_t \\
F_t \\
\end{bmatrix}
$$

(9)

There are clearly an infinite number of solutions for $x_t$ and this is to be expected when considering the literature on simultaneous equation models; premultiply any structural form by a non-singular matrix and the reduced form, (4), will be unaffected. However, $[I_2 \ I_2]P^+ y_t$, the right-hand side of the structural equation, (7), will have the general form

$$
\begin{bmatrix}
\frac{1}{|G|} \left[ g_{22} & -g_{12} \right] & R_t \\
-g_{21} & g_{11} \\
\end{bmatrix}
$$

(10)

$$
\begin{bmatrix}
\frac{1}{g_{11}} \left[ 1 + \frac{g_{21}}{|G|} \right] - \left( \frac{\beta}{g_{11}} + \frac{(g_{11} - g_{21}\beta)}{|G|} \right) \\
\left( \frac{g_{21}}{|G|} \right) \left( \frac{1}{|G|} - \frac{(g_{11} - g_{21}\beta)}{|G|} \right) \\
\end{bmatrix}
\begin{bmatrix}
m_t \\
n_t \\
\end{bmatrix}
$$

(11)

for any real values of $m_t$ and $n_t$, $t = 1, \ldots, T$. For a proof, see Section A.2. Therefore there are an infinite number of structural VARs at the $t$ period frequency that are consistent with the recursively ordered structural $t$ period VAR in (2). The top rows of (10) and (11) can be interpreted as the left-hand side of the structural return equation and the bottom rows can be interpreted as the left-hand side of the structural flow equation. However, a common choice of structural form in (7) is the Choleski solution. This essentially chooses the arbitrary values of $m_t$ and $n_t$ so that the $R_t$ term in the structural flow equation drops out. The recursively ordered structural VAR which results is just identified if the variance/covariance matrix of the residuals is assumed to be diagonal. Therefore, by choosing the Choleski solution, standard econometric methods can be used to estimate the model (OLS for example). For all other solutions though, the coefficient on contemporaneous returns in the flow equation will depend on $g_{21}$. Only if $g_{21}$ equals zero will there be no contemporaneous feedback trading. Assume $t$ represents data sampled at the 10 second frequency and $\tau$ represents data at the lower, 20 second frequency. In Section A.1, $g_{21}$ is shown to be equal to $\phi_{21}$, the coefficient on lagged returns in the flow equation in the 10 second VAR. This is perfectly intuitive. If the order flow from seconds 11 to 20 depends on the return from seconds 1 to 10, then part of the order flow from seconds 1 to 20 will depend on part of the return from seconds 1 to 20, i.e. contemporaneous feedback trading exists! The question then becomes, on what grounds should the Choleski solution be chosen? The justification for choosing the Choleski solution is always on the basis that it makes life easier; the model becomes just identified and estimation can take place simply using OLS. However, by imposing a recursive structure on the VAR, the Choleski solution rules out contemporaneous feedback trading. In this paper, we suggest that one should use the data to tell us what the coefficient on returns in the flow equation should be, rather than assuming it to be zero. In our empirical application below, we show that using data to calculate the effect of contemporaneous returns on flows, rather than assuming the coefficient to be zero, can have serious implications when calculating the price impact of trades and hence on estimates of their information content.

2. THE VAR MODEL WITH FEEDBACK TRADING

The VAR model is a convenient statistical framework that allows one to analyse the relationships between, among other things, asset returns and order flow. By interpreting order flow shocks as private information, one can examine the price impact of such shocks, via IRFs, and therefore give a quantitative estimate of the
information content of trades. The greater the price impact, the more information trades are argued to carry.

### 2.1. Model design

The standard VAR model allows asset returns to depend on contemporaneous order flows but not the converse. From Section 1, we saw that when data are aggregated, even at still very high frequencies, this recursive ordering may not be valid. Here we allow both returns and order flows to depend on each other contemporaneously. The model we wish to estimate can be written as

\[ y_t + By_t = c + \sum_{j=1}^{p} \phi_j y_{t-j} + \epsilon_t, \quad t = 1, \ldots, T \]  

where \( y_t \) is the 2×1 vector of endogenous variables at date \( t \), i.e. returns and flows; \( y_t = [R_t, F_t]' \). In Appendix A we generalize the analysis from the 2 to the \( n \)-variable case.\(^7\) \( c \) is a 2×1 vector of constants, the summation term contains the lags of the VAR and \( \epsilon_t \) is a 2×1 vector of residuals with zero mean and variance matrix \( \Omega \), assumed to be diagonal. \( B \) is the 2×2 matrix of structural parameters with zeros along the main diagonal.\(^8\)

\[ B = \begin{bmatrix} 0 & -b_{12} \\ -b_{21} & 0 \end{bmatrix} \]  

(13)

\( b_{12} \) represents the contemporaneous effect of flows on returns and \( b_{21} \) represents the contemporaneous feedback trading parameter. For each equation, \( i = 1, 2 \), we can stack the \( k \) exogenous and \( n - 1 (=1) \) endogenous regressors into a \((1+k)\times 1\) vector, \( z_{it} \). Stacking these vectors across the \( T \) observations allows us to write

\[ y_i = z_i \Pi_i + \epsilon_i, \quad i = 1, 2 \]  

(14)

\( \Pi_i \) is a \((1+k)\times 1\) vector of parameters. \( y_i \) is the \( T \times 1 \) vector of the scalar \( y_{it} \)'s \((y_{it} \in \{R_t, F_t\})\) and similarly for \( \epsilon_i \). \( z_i \) is the \( T \times (1+k) \) matrix formed by stacking the \( T, (1+k) \times 1, z_{it} \) vectors. In matrix form, (14) can be written as

\[ \begin{bmatrix} R \\ F \\ Y \\ Z \end{bmatrix} = \begin{bmatrix} z_1 \\ 0_{T \times (1+k)} \\ z_2 \end{bmatrix} \begin{bmatrix} \Pi_1 \\ \Pi_2 \end{bmatrix} + \begin{bmatrix} \epsilon^R \\ \epsilon^F \end{bmatrix} \]  

(15)

\( Y \) is \( 2T \times 1 \), \( Z \) is \( 2T \times 2(1+k) \), \( \pi \) is \( 2(1+k) \times 1 \) and \( \epsilon \) is \( 2T \times 1 \). Writing the system in this form will help us calculate the distribution of the IRFs in Section 2.3, since they will be functions of the distribution of the \( 2(1+k) \times 1 \) vector, \( \pi \).

### 2.2. Instrumental variables

Since each of the equations in (14) contain endogenous variables on the right-hand side, we estimate using instrumental variables. For the \( 1+k \) variables in \( z_{it} \) we use the \( g+k \) instruments \( w_{it}, i = 1, 2 \) and \( g \geq 1 \). For a greater explanation of the use of these variables as instruments, see Section 2.5. Using two-stage least squares, the IV estimator for \( \Pi_i, i = 1, 2 \), is denoted \( \Pi_i \) and calculated as

\[ \Pi_i = [z_i'w_i(w_i'w_i)^{-1}w_i'z_i]^{-1}z_i'w_i(w_i'w_i)^{-1}w_i'y_i \]  

(16)

where \( w_i \) is simply the \( T \times (g+k) \) matrix formed by stacking the \( T, w_{it} \) vectors of instruments. Using standard instrumental variables methods, the distribution of \( \hat{\pi} \), the \( 2(1+k) \times 1 \) vector of parameters in (15)
is given by
\[ \sqrt{T}(\hat{\pi} - \pi) \overset{d}{\rightarrow} N \left( 0, \left[ \begin{array}{cc} \sum_{\pi_1} & 0 \\ 0 & \sum_{\pi_2} \end{array} \right] \right) \]
\[ \sum_{\pi} = \sigma_e^2 Q^{-1}_{w_{1} w_{1}} Q_{w_{1} z_{i}}^{-1} \]
\[ Q_{w_{1} w_{1}} = \text{plim} \frac{1}{T} w_{1}^T w_{1} \]
\[ Q_{w_{1} z_{i}} = \text{plim} \frac{1}{T} w_{1}^T z_{i} \]  
(17)

2.3. Impulse response functions

In order to evaluate the informativeness of trades, a common approach is to use IRFs. To calculate these IRFs, we convert the VAR of (12) into its MA(∞) representation. It is simple to show that (12) can be written as
\[ y_t = \mu + \Psi_0(I_2 + B)^{-1} \epsilon_t + \Psi_1(I_2 + B)^{-1} \epsilon_{t-1} + \Psi_2(I_2 + B)^{-1} \epsilon_{t-2} + \cdots \]  
(18)

where \( \mu \) is the unconditional mean of the vector \( y_t \). \( B \) is given in (13) and \( \Psi_s, S = 0, 1, 2, \ldots \), is given by
\[ \Psi_s = (I_2 + B)^{-1} \phi_1 \Psi_{s-1} + (I_2 + B)^{-1} \phi_2 \Psi_{s-2} + \cdots + (I_2 + B)^{-1} \phi_P \Psi_{s-P} \]  
(19)

where \( \phi_j, j = 1, \ldots, P, \) are the coefficients on the lags in the VAR in (12) and \( \Psi_0 = I_2 \), the 2 \( \times \) 2 identity matrix. \( \Psi_k = 0_{2 \times 2} \forall k < 0 \). The impacts of \( \epsilon_t \) on \( y_{t+s} \) are shown by the IRFs, \( H_s \), where \( H_s \) is the 2 \( \times \) 2 coefficient matrix on \( \epsilon_{t-s} \) in (18).

\[ H_s = \Psi_s(I_2 + B)^{-1} \]  
(20)

We therefore introduce a one unit order flow shock to each of the VARs and examine the effect of the feedback trading parameter by comparing the IRFs with and without this feedback trading. In order to determine whether the non-feedback IRF is significantly different from the IRF of the unrestricted VAR, we have to calculate the distribution of this feedback impulse response and we do so analytically using the delta method.\(^{10}\) From (20), \( H_s \) depends only on the parameters in the structural VAR, the distribution of which is given in (17). If \( H_s = \tilde{\Psi}_s(I_2 + B)^{-1} \), where \( \tilde{\Psi}_s \) is the estimate of \( \Psi_s \), then the distribution of the IRF parameters is given, using (17), as
\[ \sqrt{T}(H_s - h_s) \overset{d}{\rightarrow} N(0, G_s \Sigma_s G_s') \]  
(21)

where \( G_s \) is 4 \( \times \) 2(1 + \( k \)) and equals \( \partial h_s / \partial \pi' \). However, to calculate \( G_s \), one cannot use the results of Hamilton (1994). The structural VARs considered in Hamilton (1994) are estimated from the reduced form and the structural parameters are back out from the variance/covariance matrix of the residuals. In that way, the distribution of the IRFs depends, not only on the distribution of the reduced form parameters, but also on the distribution of the variance/covariance matrix of the errors. Since we use instrumental variables to estimate the structural parameters directly, the distribution of the IRFs in (21) will depend only on the distribution of the \( \pi \) parameters and not on the distribution of the variance/covariance matrix of residuals. Using methods similar to Hamilton (1994) and Lütkepohl (1990), \( G_s \) can be written as\(^{11}\)

\[ G_s = \frac{\partial h_s}{\partial \pi'} = [I_4 + (I_2 \otimes B')]^{-1} \left[ \frac{\partial \Psi_s}{\partial \pi'} - (H_s \otimes I_2) S_B \frac{\partial \Omega_{y'}}{\partial \pi'} \right] \]  
(22)

where \( S_B \) and \( \partial \Omega_{y'}/\partial \pi' \) are shown to be matrices of zeros and ones, and \( \partial \Psi_s / \partial \pi' \) is given by
\[ \frac{\partial \Psi_s}{\partial \pi'} = - (I_2 \otimes \left( [\phi_1 \Psi_{s-1} + \cdots + \phi_P \Psi_{s-P}] \right) \left( (I_2 + B)^{-1} \otimes \left( (I_2 + B)^{-1} \right) \right) S_B \frac{\partial \Omega_{y'}}{\partial \pi'} \]
\[ + \sum_{j=1}^{P} \left\{ (I_2 + B)^{-1} \otimes \Psi_j^{-1} \frac{\partial \Omega_{y'}}{\partial \pi'} + ((I_2 + B)^{-1} \phi_j \otimes I_2) \frac{\partial \psi_{s-j}}{\partial \pi'} \right\} \]  
(23)

where again, \( \partial \Omega_{y'}/\partial \pi', j = 1, \ldots, P, \) are matrices of zeros and ones. Using (21)–(23) we can then calculate the distribution of the IRFs and therefore see whether the restricted/non-feedback IRF is significantly different from the unrestricted impulse response.\(^{12}\)
2.4. Data

The market we consider is that of the spot USD/EUR (US dollar per euro) inter-dealer foreign exchange market, taken from the Reuters D2000-2 electronic trading system. The data we consider as instruments are those from the USD/GBP (US dollar per pound sterling) and GBP/EUR (pound sterling per euro). When sampling the data we record the last transaction price in each period (1 or 5 minutes) and the order flow, defined as the number of buyer-initiated trades minus the number of seller-initiated trades. Unfortunately, we have no information on traded quantities. However, to the extent that earlier work has shown little size variation in trades on this dealing system (Payne, 2003) and that in other applications it is the number rather than aggregate size of trades that has been shown to matter for prices and volatility (Jones et al., 1994), we expect that this limitation will not distort our results. Furthermore, even when both the number and size of trades have been available, research has often focussed on the former measure of trading activity (Hasbrouck 1991). We also decide to remove certain sparse trading periods from our sample. These include weekends, the overnight period, defined as 1800 to 0600 GMT (BST in the summer months) where trading activity was found to be very thin and some public holidays including Christmas, New Year, Easter (Good Friday and Easter Monday) and the May Day bank holiday. Periods where the D2000-2 data feed broke down were also excluded. These periods are defined as those where no transactions (and hence no price changes) occurred for at least 30 minutes during the day in any of the three FX markets, i.e. if the data feed broke down on GBP/EUR or USD/GBP but not USD/EUR then those data are still excluded, purely because the GBP/EUR and USD/GBP data are needed in the construction of the instruments. This filtering process reduced the total number of observations to 90,949 at the 1 minute frequency and 18,401 at the 5 minutes frequency. Table 1 contains statistical information on exchange rate returns, defined as 100 times the logarithmic difference in prices, transaction frequencies and order flows for our filtered data sample.

2.5. Instrumenting the endogenous variables

The IV estimator and its distribution, reported in Section 2.2, are standard results. The main question at this point concerns what instruments one can use and how good they are at instrumenting the endogenous regressors. Since the data available to us include not only USD/EUR returns and transactions but also those from the USD/GBP and GBP/EUR markets, the statistics from these other two markets seem prime candidates for use as instruments. Previous research has documented the cross-effects of order flow on exchange rates. Evans and Lyons (2002a) document the role that order flow in one currency has in determining exchange rates in other markets. In particular DEM/USD (Deutsche marks per dollar) and

Note: The USD/EUR exchange rate is defined as the number of dollars (numerator currency) per euro (denominator currency). Returns are defined as 100 times the first difference of the logarithm of the exchange rate. Positive order flow in the USD/EUR market implies net purchases of euro.
*Significance at the 5% level or less.
CHF/USD (Swiss francs per dollar) order flows have significant effects on a number of other dollar exchange rates. These cross-market effects are also documented in Danielsson et al. (2002) which considers the USD/EUR, GBP/EUR, USD/GBP and JPY/USD markets. Theoretical explanations as to why cross-effects of order flow exist are also presented in Lyons and Moore (2003), which examines the triangle of rates between the US dollar, euro and yen.

Since the triangle of rates between the dollar, sterling and euro form a strict cointegrating system, using contemporaneous USD/GBP and GBP/EUR returns as instruments for USD/EUR returns is likely to be problematic. Following a shock to USD/EUR returns at date $t$ for example, this will affect not only the USD/EUR rate but also one or both of the sterling rates, otherwise clear arbitrage opportunities would result. In which case date $t$ USD/GBP and GBP/EUR returns will be correlated with the date $t$ error in the USD/EUR return equation. The use of contemporaneous USD/GBP and GBP/EUR returns as instruments for the endogenous USD/EUR variables will then result in biased parameter estimates just as OLS estimates would. Instead, we consider lags of sterling returns which should not be correlated with the errors and hence stand a good chance of being valid instruments.

Also, under conditions of no arbitrage, it is clear that the USD/EUR return at time $t$ will equal the sum of the returns in the USD/GBP and GBP/EUR markets. Therefore, using lags of both sterling returns as instruments will be problematic since, unless the coefficients on the sterling returns are different in the first-stage regression in the 2SLS procedure, we will essentially be using a ‘synthetic’ lagged USD/EUR return to instrument for contemporaneous returns. However, the lagged USD/EUR return is effectively being used as an instrument for itself, since it too is included in the VAR. For this reason we only use one of either USD/GBP or GBP/EUR returns as instruments. Which return series we use will depend on how good they are at instrumenting for the endogenous regressors. Since the no arbitrage problem does not hold for our order flow series; USD/EUR order flow in period $t$ does not have to equal the sum of the USD/GBP and GBP/EUR flows, we consider both USD/GBP and GBP/EUR order flows as candidate instruments for the contemporaneous USD/EUR flow regressor.

Researchers have often pointed to the pitfalls of using weak instruments and the bias that such instruments introduce. See for example Buse (1992), Bound et al. (1995), Wang and Zivot (1998), and Staiger and Stock (1997). It is therefore vital that we examine the quality of our instruments. In our two equation case, in returns and flows, we only have one endogenous regressor and so test the quality of our instruments using the procedure discussed in Pagan and Robertson (1998). They suggest an easily implementable test for the quality of potential instruments by means of a Wald test. For cases with multiple endogenous regressors, see Shea (1996) and Hall et al. (1996). The Wald test is essentially a test of the overidentifying restrictions in the model. One could write model (12) with other right-hand side explanatory variables, including GBP/EUR and USD/GBP returns and flows, the cross-market effects of which are documented in Danielsson et al. (2002). By imposing ‘zero’ restrictions on the variables, they can be used to instrument the endogenous regressors, and the Wald test is essentially testing these overidentifying restrictions in the reduced form VAR. The results of these Wald tests are reported in Table 2 for the 1 and 5 minute frequency VARs.

For the 1 minute frequency VAR, three lags of USD/GBP and GBP/EUR flows were chosen to instrument for USD/EUR flows in the return equation, while two lags of USD/GBP returns were chosen as instruments for USD/EUR returns in the flow equation. Testing the quality of the instruments for USD/EUR flows in the return equation produced a Wald test of 28.09. For returns in the flow equation, the instrument Wald test was 236.13. The 1% critical values for the corresponding $\chi^2$ distributions are 16.81 and 9.21, respectively, suggesting that the chosen variables are good instruments for the endogenous regressors. When considering the 5 minute frequency VAR, contemporaneous and one lag of both USD/GBP and GBP/EUR flows were chosen to act as instruments for USD/EUR flows in the return equation, while in the flow equation, two lags of GBP/EUR returns were chosen to instrument for USD/EUR returns. The regression of USD/EUR flows on all exogenous variables and instruments produced a Wald test of 7109.01, while testing how good the GBP/EUR returns are as instruments for returns in the flow equation produced a Wald test of 62.26. Again both of these are significant at the 1% level, suggesting that these variables make good instruments. We also considered sampling the data at lower frequencies.
However, at anything lower than the 5 minute frequency, the instrument Wald test became insignificant, even at the 5% level, suggesting that neither USD/GBP or GBP/EUR variables would be good at instrumenting for the endogenous USD/EUR returns and flows. Since only lagged returns are suggested as instruments, due to the problems of using contemporaneous USD/GBP and GBP/EUR returns explained above, as soon as one considers lower frequency data, the ability of these lagged variables to instrument for USD/EUR returns is likely to fall. At the hourly or daily frequency for example, returns and flows will no longer be serially correlated. If USD/EUR returns are not correlated with its own lag, it is highly unlikely that they will be correlated with the lags of USD/GBP or GBP/EUR returns. At the lower frequencies, even the 15 minute level, the candidate instruments became very weak. Therefore the estimations were only performed for the 1 and 5 minute VARs.

To our knowledge, only one other paper has tried to examine contemporaneous feedback trading in the foreign exchange market. Evans and Lyons (2003) use a VAR model, as we do, in returns and order flows but is not as general as the procedure outlined above. Evans and Lyons split order flows into two types, both having different roles. They assume returns depend on contemporaneous ‘informational’ trades while ‘feedback’ trades depend on contemporaneous returns. The order flow measure available from the data is simply the sum of these two components. This is more restrictive than our approach since we do not, in any way, split trades into different motives. By using variables obtained from other FX markets as instruments we are able to estimate an otherwise unidentified model.\textsuperscript{16}

\textit{Note:} $R_{t}^{x}$ is 100 times the log first difference of exchange rate $x$ at date $t$. $F_{t}^{x}$ is the order flow for exchange rate $x$, defined as the number of buyer less the number of seller initiated transactions in period $t$. 

Without feedback trading, the explanatory power of lagged returns and three for order flows. Each VAR was estimated equation by equation and heteroscedasticity consistent standard errors were calculated using the Newey–West method. The lag lengths of the VAR were chosen using the Schwartz Information Criterion and this resulted in seven lags of returns and one of order flows. Each VAR was estimated equation by equation and the Newey–West method was used to correct for heteroscedasticity. The Schwartz Information Criterion suggested using three lags of returns and three for order flows. Each VAR was estimated equation by equation and heteroscedasticity consistent standard errors were calculated using the Newey–West method. The left panel shows the estimation results of the feedback VAR. There are a number of important findings. Firstly, as one would expect, returns depend positively on contemporaneous order flow. One way buying (selling) pressure causes positive (negative) returns intraminute. Returns also display negative serial correlation, as have been found in Payne (2003) and Evans (2002), both of whom consider the DEM/USD market. Returns also depend negatively on lagged own order flow, although the explanatory power of these variables in the determination of returns is surprisingly low compared to previous studies; the $R^2$ is only 11.2%. Of more interest in this paper are the results for the order flow equation. Order flow appears to depend positively on contemporaneous returns, with a coefficient that is significant at the 1% level. This suggests that following a positive return in 1 minute, traders ‘buy into’ the currency in that same period, possibly because they expect further price changes in the same direction. However, this is not consistent with the negative serial correlation observed in 1 minute returns. On the other hand, positive intraminute feedback trading is consistent with the positive effect of lagged returns on order flows, seen in both versions of the VAR. This lagged feedback trading phenomenon is considered in more detail by Cohen and Shin (2003) in the US treasury market. Without feedback trading, the $R^2$ in the flow equation is only 8.2%. However, when contemporaneous feedback trading is allowed, the $R^2$ increases to 26.5%, suggesting that contemporaneous price changes are an important determinant of order flows.

Table 4 gives the VAR results when the data are sampled at the 5 minute frequency. Again the VARs were estimated equation by equation and the Newey–West method was used to correct for heteroscedasticity. The Schwartz Information Criterion suggested using three lags of returns and one of flows. The results are similar, but more pronounced, than those from the higher/1 minute frequency VAR. Again, order flows have a positive and significant effect on contemporaneous returns, as one would expect, and returns display negative serial correlation and depend negatively on lagged flows. The explanatory power
of these variables for 5 minute returns is quite high, with an $R^2$ of 31.1%. When examining the flow equation, we again find evidence of feedback trading. Flows depend positively, not only on lagged returns, but also on contemporaneous 5 minute returns. The coefficient on contemporaneous returns in the flow equation is significant at the 5% level and quantitatively very large; the size of the contemporaneous feedback trading parameter is more than two and a half times larger than that on the first lag of returns (56.27 versus 21.23). Indeed, if there is positive feedback trading (lagged and contemporaneous) at the 1 minute frequency, this, by definition, will be shown as contemporaneous feedback trading at the 5 minute frequency, as demonstrated in Section 1. The results therefore suggest that positive feedback trading is present in the spot USD /EUR market and significant at high frequencies. Intraminute feedback trading is significant but not large, possibly because of the time it takes for traders to react to the price movements. At the 5 minute frequency, however, intraperiod feedback trading becomes much larger as any lagged feedback trading at higher frequencies gets incorporated into the contemporaneous feedback effect. We can interpret the effects of this feedback trading using standard VAR analysis, namely IRFs. This is the focus of the next section.

3.1. Implications of contemporaneous feedback trading: impulse response functions

We follow standard practice and use IRFs to estimate the information content of trades. Shocking the system with an order flow shock, $e_i$, where $i$ corresponds to the order flow equation in (12), can be interpreted as examining the effect of private information. The larger the impact such a shock has on returns, the more informative order flows are argued to be. By comparing the IRFs following an order flow shock in the two VARs (feedback trading versus non-feedback trading) we can examine how important contemporaneous feedback trading is. Intuitively, by ignoring the positive feedback trading (in the recursively ordered structural VAR) it is likely that any order flow shock will have a smaller impact on returns. The existence of positive feedback trading will cause the price impact of order flow shocks/private information to be larger than when feedback trading is ignored, i.e. trades carry more information than previous estimates suggest.

The IRFs following a one unit order flow shock are shown in the top panel of Figure 1 for the 1 minute frequency VAR. A number of features can be noted.

- The impact of the order flow shock is almost immediate. Following the one unit shock in the feedback VAR, this causes a 1.09 basis point return and after 10 minutes the cumulative return is 1.06 basis points.
- When contemporaneous feedback trading is allowed, the effect of the order flow shock is larger than when contemporaneous feedback trading is prohibited; the feedback impulse response is more than

Note: The data cover the 8-month period from 1 December 1999 to 24 July 2000. The USD/EUR exchange rate is defined as the number of dollars (numerator currency) per euro (denominator currency). Returns are defined as 100 times the log first difference of the exchange rate. Positive order flow in the USD/EUR market implies net purchases of euro. a, b denote significance at the 1% and 5% levels, respectively. Newey–West-corrected $T$-stats in parentheses.
double that in the non-feedback VAR. However, the non-feedback VAR IRF is not significantly different from the feedback IRF, i.e. the non-feedback IRF lies within the 95% confidence bound of that from the unrestricted VAR.\footnote{20}

This suggests that at the 1 minute frequency, the difference between the two impulse response functions is economically significant, if not statistically so (at the 5% level). Evaluating the informativeness of order
flows by considering their price impact will result in a bias if a recursively ordered VAR is considered. However, the statistical significance of this bias is questionable.\textsuperscript{21}

The results from the 5 minute frequency VAR are more pronounced and suggest a much more important role for feedback trading in the interpretation of IRFs. The IRFs following a one unit order flow shock are shown in the bottom panel of Figure 1. The notable features are given below.

- On impact of the order flow shock in the feedback VAR, this causes a return of 1.12 basis points. The cumulative return is 1.02 basis points after 30 minutes.
- Again, as in the 1 minute VAR results, the effect of a one unit order flow shock is larger when feedback trading is allowed. On impact of the order flow shock in the non-feedback VAR, the return is only 0.43 basis points, i.e. the feedback IRF is over two and a half times that of the non-feedback VAR. However, for the 5 minute frequency case, the non-feedback IRF is significantly different from the unrestricted impulse response, i.e. it lies outside the 95\% confidence bound.

Therefore, at the 5 minute frequency, feedback trading appears to have important consequences when trying to calculate the price impact/informativeness of order flow. The IRF that is commonly computed (that does not allow contemporaneous feedback trading) is significantly below the ‘true’ IRF which does allow such trading strategies. The price impact of order flow, and hence proxies for the informativeness of such trades, is therefore larger than is commonly believed, implying that trades carry more information than previous studies suggest. The feedback trading that occurs both contemporaneously and also with lags at the 1 minute frequency, has significant repercussions when modelling 5 minute data without feedback trading, as is commonly done.

4. DISCUSSION AND INTERPRETATION

We have shown that feedback trading in the USD/EUR spot FX market does exist even at high frequencies, specifically the 1 and 5 minute sampling frequencies. At the 1 minute frequency, even though the non-feedback impulse response is not different from the unrestricted IRF in a statistical sense, it is different in an economic sense; the feedback impulse response is more than twice that of the non-feedback IRF, implying trades carry over twice as much information than current estimates suggest. At the 5 minute frequency, the contemporaneous effect of returns on order flows is significant and causes the IRFs with and without feedback trading to differ significantly, economically and statistically. Indeed, if feedback trading occurs at the 1 minute frequency in the lags and also contemporaneously, then by definition, such trading strategies will appear contemporaneous at the 5 minute frequency. This positive feedback trading causes the price impact of unanticipated order flow shocks (representing private information) to be larger compared to when contemporaneous feedback trading is ruled out. The price impact of private information/order flow shocks that is commonly calculated will then be biased downwards compared with the true impact.

In this paper, we have labelled the effects of contemporaneous asset returns on order flows as feedback trading effects. However, there may be other reasons why date $t$ order flows depend on contemporaneous asset returns. Firstly, traders wishing to trade large quantities may break up their trade into a number of smaller sized transactions. By walking up and down the limit order book and splitting a large buy order into a number of smaller trades, to be executed within a short time interval, this will be shown up in the VAR as order flows depending on contemporaneous asset returns. Even though traders are not ultimately wishing to trade based on previous price changes; the decision to trade was made some time earlier, this will still manifest itself as date $t$ order flow depending (statistically) on date $t$ asset returns. However, if traders split up their orders and work them through gradually over time, then the contemporaneous effect of returns on orders caused by order splitting will wash out as one considers longer and longer sampling frequencies. Unfortunately, we are only able to consider very high frequencies in this study due to the limited applicability of our instruments. Using the methodology of Rigobon and Sack (2003), whereby the changing relative heteroscedasticity of the data is used to identify the structural parameters, one may be able to estimate the structural models of asset returns and order flow determination at longer horizons.
Therefore, one may be able to decompose the contemporaneous effect of returns on order flow, depending on how long it takes for traders to split up and work through an order. We leave this for future research.

Another reason why order flow may appear dependent on contemporaneous returns in aggregated data is because of the existence of stop-loss orders (Osler, 2002). If the price of an asset falls to a certain level, traders may initiate sell orders in order to stop losses from getting any larger. In which case, negative (positive) returns induce negative (positive) order flow immediately. In any case, what we have demonstrated in this paper is that order flow at date \( t \) depends positively on date \( t \) asset returns in the spot FX market. Whether this is due to the splitting of dealers’ trades, stop loss orders or due to ‘pure’ feedback trading based on extrapolative expectations of future price changes, is irrelevant. In all cases, the assumption of a recursively ordered structural VAR will result in a misspecified model and in a bias in any estimate of the price impact/informativeness of trades.

This paper does not try to explain why feedback trading may occur in the foreign exchange market, or indeed how profitable such strategies may or may not be. The purpose of the paper is to analyse the effects of contemporaneous feedback trading on estimates of the price impact of order flows. Such measures are commonly used as proxies for the informativeness of trades (how much information trades carry). As shown in this study, these measures are underestimated if feedback trading is ignored and the data are sampled at anything other than at the highest frequencies. Following a positive order flow shock, representing private information, this causes a positive return due to the asymmetric information (Kyle, 1985; Glosten and Milgrom, 1985) or inventory control channels (Lyons, 1995). If such price changes induce further trades, which in turn cause price changes, etc., then the total effect of the order flow shock will be greater than when contemporaneous feedback trading is prohibited.

At the 5 minute frequency we find that after a one unit order flow shock, this causes a return of approximately 1.12 basis points whereas when feedback trading is ignored, the return is only 0.43 basis point. The non-feedback IRF is significantly different from that of the unrestricted VAR, implying that feedback trading makes a difference when calculating the price informativeness of trades.

5. CONCLUSIONS

Microstructure theory suggests that trades carry information and hence have permanent effects on prices. The information content of these trades is normally quantified by examining their price impact (Hasbrouck, 1991) after fitting the data to a vector autoregression. However, common practise is to allow returns to depend on contemporaneous order flows but not the converse. The recursively ordered structural VAR that results can then be estimated quite easily. Although intuitive at ultra-high frequencies, such as tick-by-tick, as soon as one starts aggregating the data, any feedback trading (that by definition can only occur in the lags of tick-by-tick data) will appear contemporaneous. The recursively ordered VAR then becomes misspecified and can have important repercussions when examining the price impact of order flow shocks. In this paper, we use standard instrumental variables techniques in order to estimate a VAR model that allows contemporaneous feedback trading. Feedback trading is found to be significant and positive at the 1 and 5 minute frequencies, with the implication that the price impact of order flows is underestimated when such trading strategies are not allowed. Trades, in the form of order flow shocks, therefore carry more information/have a larger impact on asset prices than previously believed.

APPENDIX A

A.1. Aggregation of the ultra-high frequency VAR in model (1)

The methods used here are taken from Harvey (1989). Let \( \tau \) denote timing at the 20 second frequency, \( \tau = 1, \ldots, T \), and \( t \) denote timing at the 10 second frequency, \( t = 1, \ldots, 2T \). The reduced form of the 10 second frequency VAR is then given in (3). For convenience, this is given in (A1).

\[
y_t = Q^{-1}z + Q^{-1}\phi y_{t-1} + Q^{-1}e_t, \quad t = 1, \ldots, 2T
\]  
(A1)
Let $\mu$ denote the unconditional mean of the stationary vector process, $y_t$. In which case we can write

$$y_t - \mu = Q^{-1}\phi(y_{t-1} - \mu) + Q^{-1}e_t$$

(A2)

Putting (A2) into state space form, gives the state and observation equations as (A3) and (A4), respectively.

$$\begin{bmatrix} y_{t+1} - \mu \\ y_t - \mu \end{bmatrix}_t = \begin{bmatrix} Q^{-1}\phi & 0 \\ I_2 & 0 \end{bmatrix}_{F} \begin{bmatrix} y_{t-1} - \mu \\ y_{t-1} - \mu \end{bmatrix}_t + \begin{bmatrix} u_{t+1} \\ v_{t+1} \end{bmatrix}_t$$

(A3)

$$\text{Var}(v_{t+1}) = \Sigma = \begin{bmatrix} Q^{-1}\Omega(Q^{-1})' & 0 \\ 0 & 0 \end{bmatrix}_{y_t}$$

(A4)

If $y^f_t$ denotes the cumulator variable, i.e. $y^f_t = y_t$ for the first 10 seconds of a 20 second period and $y^f_t = y_t + y_{t-1}$ for the second 10 second period, then

$$y^f_{2(t-1)+1} = y_{2(t-1)+1}$$

$$y^f_{2(t-1)+2} = y_{2(t-1)+1} + y_{2(t-1)+2}$$

(A5)

The cumulator variable at the 10 second frequency, but at times $t = 2, 4, 6, \ldots$, can therefore be given, using the observation equation, (A4), as

$$y^f_t = y^f_{t-1} + \mu + H'F\xi_{t-1} + H'v_t$$

(A6)

At times $t = 1, 3, 5, \ldots$, the cumulator variable is given by

$$y^f_{t-1} = \mu + H'\xi_{t-1}$$

(A7)

Substituting $y^f_{t-1}$ into (A6) and using $\xi_{t-1} = F\xi_{t-2} + v_{t-1}$ gives

$$y^f_t = 2\mu + H'(F + F^2)\xi_{t-2} + H'(I_2 + F)v_{t-1} + H'v_t$$

$$\text{Var}(\tilde{v}_f^t)$$

(A8)

Since the cumulator function, $y^f_t$, at times $t = 2, 4, 6, \ldots$, is the same as $y_t$, the data sampled at the 20 second frequency, then we can write

$$y_t = 2\mu + H'(F + F^2)\begin{bmatrix} y_{t-1} - 2\mu \\ y_{t-2} - 2\mu \end{bmatrix} + H'\tilde{v}_f$$

(A9)

Noting that $H'(F + F^2) = [Q^{-1}\phi(I_2 + Q^{-1}\phi) 0]$ then the reduced form model at the 20 second frequency can be written as

$$y_t = (I_2 - Q^{-1}\phi(I_2 + Q^{-1}\phi))2\mu + Q^{-1}\phi(I_2 + Q^{-1}\phi)y_{t-1} + e_t$$

(A10)

where $e_t = [I_2 0]\tilde{v}_f^t$. \text{Var}(e_t) is therefore given by

$$\text{Var}(e_t) = [I_2 0]\text{Var}(\tilde{v}_f^t) \begin{bmatrix} I_2 \\ 0 \end{bmatrix} = [I_2 0]([I_2 + F]\Sigma(I_2 + F)' + \Sigma) \begin{bmatrix} I_2 \\ 0 \end{bmatrix}$$

$$= (I_2 + Q^{-1}\phi)Q^{-1}\Omega(Q^{-1})'(I_2 + Q^{-1}\phi)' + Q^{-1}\Omega(Q^{-1})'$$

$$= G\Omega G' + Q^{-1}\Omega(Q^{-1})'$$

(A11)
where \( G = (I_2 + Q^{-1} \phi)Q^{-1} \). Expanding this gives us the elements of \( G \).

\[
G = \begin{bmatrix} g_{11} & g_{12} \\ g_{21} & g_{22} \end{bmatrix} = \begin{bmatrix} 1 + \phi_{11} + \beta \phi_{21} & (1 + \phi_{11} + \beta \phi_{21}) \beta + \phi_{12} + \beta \phi_{22} \\ \phi_{21} & \phi_{12} + \beta \phi_{22} \end{bmatrix}
\]

(A12)

### A.2. Derivation of the structural form of the 20 second VAR

The structural VAR at the 20 second frequency is given in (7) and \( x_t, i = 1, \ldots, 4 \), can be found using Gaussian elimination, resulting in

\[
x_{1t} = \left( \frac{1}{g_{11}} + \frac{g_{12}g_{21}}{|G|} \right) R_t - \left( g_{12} \frac{g_{11}}{|G|} \right) F_t - \left( \frac{1}{g_{11}} - \frac{g_{21}}{|G|} \right) m_t - \left( \frac{\beta}{g_{11}} + \frac{g_{11} - g_{21} \beta}{|G|} \right) n_t
\]

\[
x_{2t} = -\left( g_{21} \frac{g_{11}}{|G|} \right) R_t + \left( g_{11} \frac{g_{11}}{|G|} \right) F_t + \left( \frac{g_{21}}{|G|} \right) m_t - \left( g_{11} - g_{21} \beta \right) n_t
\]

(A13)

\[
x_{3t} = m_t
\]

\[
x_{4t} = n_t
\]

for any real values of \( m_t \) and \( n_t, \tau = 1, \ldots, T \), implying an infinite number of solutions. The right-hand side of (7) can be written as \( [I_2 I_2] x_t \), and the coefficients on \( R_t \) and \( F_t \) are the structural parameters of interest. Noting that \( [I_2 I_2] x_t = [x_{1t} + x_{3t}] [x_{2t} + x_{4t}] \) gives us (10).

## ACKNOWLEDGEMENTS

Thanks to the Bank of England for providing the transactions data used in this study. Financial assistance from the Economic and Social Research Council is gratefully acknowledged (grant number L138251036). The paper has also benefitted from comments by Greg Connor, Charles Goodhart, Andrew Patton, Mark Taylor, Rich Lyons and seminar participants at Warwick Business School and Aix en Provence. All errors are the joint responsibility of the authors.

## NOTES

1. Blanchard and Quah (1989) suggest another restriction for identification; that one type of shock has no long run effect on one of the other variables. This assumption cannot be used in this setting. Order flow shocks are likely to have permanent effects on the asset price, as in the models of Kyle (1985), etc., and asset return shocks are likely to have non-zero long run effects on cumulative order flow due to reasons of portfolio rebalancing for example.

2. The other electronic trading system is that of EBS and together they account for between 85% and 95% of all interdealer trading. See Bank for International Settlements (2001).

3. When the data were sampled at lower frequencies the abilities of other market statistics to instrument for USD/EUR endogenous variables deteriorated to such an extent that such analysis became pointless.

4. For the purpose of this study we simply wish to examine data at a frequency where no contemporaneous feedback trading can occur and then see what happens when we aggregate the data at a lower frequency.

5. For example, \( t \) could represent data sampled at the 10 second frequency and \( \tau \) would represent data sampled at the 20 s frequency.

6. Note that the errors in the return and flow equations at the \( \tau \) period frequency are serially uncorrelated and independent, as too are those at the \( t \) period frequency.

7. In the model of Engle and Patton (2004), returns of ask prices and returns of bid prices are considered separately, so \( y_t \) need not be restricted to be a \( 2 \times 1 \) vector. In the original Hasbrouck (1991) setting, \( y_t \) also contained a number of trade-related variables including trade sign and the interactions between trade sign and volume and spread.

8. We separate \( y_t \) and \( B_t \) in (12) as this simplifies the notation when we calculate the distribution of the IRFs.

10. Confidence intervals for IRFs can also be found using numerical methods (bootstrapping). However, this proved to be problematic in this exercise due to the difficulties of bootstrapping instruments—the procedure suggested by Freedman (1984) proved unsuccessful. Instead, analytical expressions for confidence intervals were found. Runkle (1987) shows that this technique works reasonably well. See also Watson (1994).

11. A derivation of the following is available from the authors on request.

12. The distribution of the cumulative IRFs can be calculated quite easily from (21). See Lütkepohl (1990).
13. Also available in the dataset are the numbers of buyer- and seller-initiated trades separately. One may have thought that trading volume could be used as an instrument. Unfortunately, this is not the case. By splitting up order flow into ‘buys’ and ‘sells’, it becomes clear that although the order condition is satisfied, the rank condition is not.

14. To test the quality of our instruments, we run a regression of the endogenous regressor in each of the structural equations in (12) on all the exogenous variables (lagged USD/EUR flows and returns) as well as the candidate instruments. A Wald test is then performed on the coefficients of those instruments. For the endogenous USD/EUR return regressor we begin by using the first lag of either USD/GBP or GBP/EUR returns and continue increasing the lag length of the instruments until no more explanatory power is added by their inclusion. The choice as to which sterling series to use, is made based on the overall fit of this first-stage regression. For the USD/EUR flow regressor, we start by considering contemporaneous USD/GBP and GBP/EUR flows and increase the lag length in a similar fashion.

15. It may appear strange that different variables were chosen to act as instruments at the 1 and 5 minute frequencies. This may be reconciled when one considers the different FX market dynamics at the different frequencies. With different dynamics and cross-correlations at 1 and 5 minute frequencies, it may be unsurprising to find different choices of instruments. The question of which variables to include as instruments is, after all, an empirical one. The huge Wald statistic on the instruments for USD/EUR flows (7109.01) comes primarily from the use of contemporaneous USD/GBP and GBP/EUR flows as instruments. Surprisingly, contemporaneous flows were not of any use for the 1 minute VAR, suggesting possibly delayed information spill-overs from one market to another.

16. At the daily frequency, Evans and Lyons (2003) find evidence of negative feedback trading!

17. The feedback VAR was estimated equation by equation using instrumental variables, described above, while the recursively ordered/non-feedback VAR was estimated equation by equation using OLS. In this way, we compare the ‘true’, unrestricted VAR to that which would have been estimated using current best practice.

18. This raises the question of how good lagged sterling flows are at instrumenting for contemporaneous USD/EUR flows at the 1 min frequency. The dramatic reduction in $R^2$ from non-feedback to feedback VAR, along with the dramatic reduction in the t-stat on contemporaneous flows, suggests either a huge mis-specification in the non-feedback VAR, or the use of instruments which are not as strong as the Wald test suggests. However, this problem is not apparent in the 5 minute frequency VAR, in which the feedback trading parameter is larger and makes more of a difference.

19. For the 1 minute VAR, contemporaneous feedback trading had a coefficient of 27.02, compared with 24.12 for the first lag of returns.

20. Impulse responses were also done using a one standard deviation order flow shock but this had no effect on our results. This is because the standard deviations of order flow shocks were very similar in both VAR specifications; see Table 3.

21. As reported in footnote 18, the results for the 1 minute VAR may be open to question if the instruments are not as good as the Wald test suggests.
